

Chapter 6: Viscous Flow in Ducts

6.2 Stability and Transition

Stability: can a physical state withstand a disturbance and still return to its original state.

In fluid mechanics, there are two problems of particular interest: change in flow conditions resulting in (1) transition from one to another laminar flow; and (2) transition from laminar to turbulent flow.

(1) Transition from one to another laminar flow

(a) Thermal instability: Bernard Problem

A layer of fluid heated from below is top heavy, but only undergoes convective “cellular” motion for

$$\text{Rayleigh \#}: \quad Ra = \frac{g\alpha\Gamma d}{\nu w/d^2} = \frac{g\alpha\Gamma d^4}{k\nu} > Ra_{cr} \quad \frac{\text{bouyancy force}}{\text{viscous force}}$$

$$\alpha = \text{coefficient of thermal expansion} = -\frac{1}{\rho} \left(\frac{\partial \rho}{\partial T} \right)_p$$

$$\Gamma = \Delta T / d = -dT/dz \quad \rho = \rho_0(1 - \alpha\Delta T)$$

d = depth of layer

k, ν = thermal, viscous diffusivities

*w=velocity scale: convection ($w\Gamma$) = diffusion ($k\Gamma/d$)
 from energy equation, i.e., $w=k/d$*

Solution for two rigid plates:

$Ra_{cr} = 1708$ for progressive wave disturbance

$$\alpha_{cr}/d = 3.12 \quad w = \hat{w} e^{i\alpha(x-ct)} = e^{c_i t} [\cos(x-ct) + \sin(x-ct)]$$

$$\lambda_{cr} = 2\pi/\alpha = 2d \quad T = \hat{T} e^{i\alpha(x-ct)}$$

$$\alpha = \alpha_r \quad c = c_r + i c_i \quad \text{For temporal stability}$$

$\alpha_r = 2\pi/\lambda = \text{wavenumber}$

$c_r = \text{wave speed}$

*$c_i : > 0$ unstable
 $= 0$ neutral
 < 0 stable*

**$Ra > 5 \times 10^4$ transition
 to turbulent flow**

Thumb curve: stable for low $Ra < 1708$ and very long or short λ .

Fig. 11.2 Definition sketch for the Bénard problem.

Fig. 11.3 Flow pattern and eigenfunction structure of the gravest even mode and the gravest odd mode in the Bénard problem.

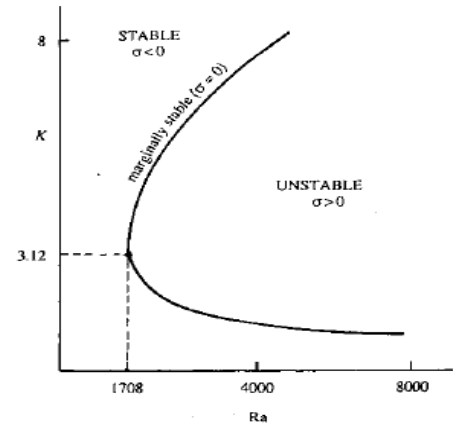

Fig. 11.4 Stable and unstable regions for Bénard convection.

Fig. 11.5 Convection rolls in a Bénard problem.

(b) finger/oscillatory instability: hot/salty over cold/fresh water and vice versa.

$$(Rs - Ra)_{cr} = 657$$

$$Rs = g\beta d^4 (ds/dz) / \nu k_s$$

$$\rho = \rho_0 (1 - \alpha\Delta T + \beta\Delta S)$$

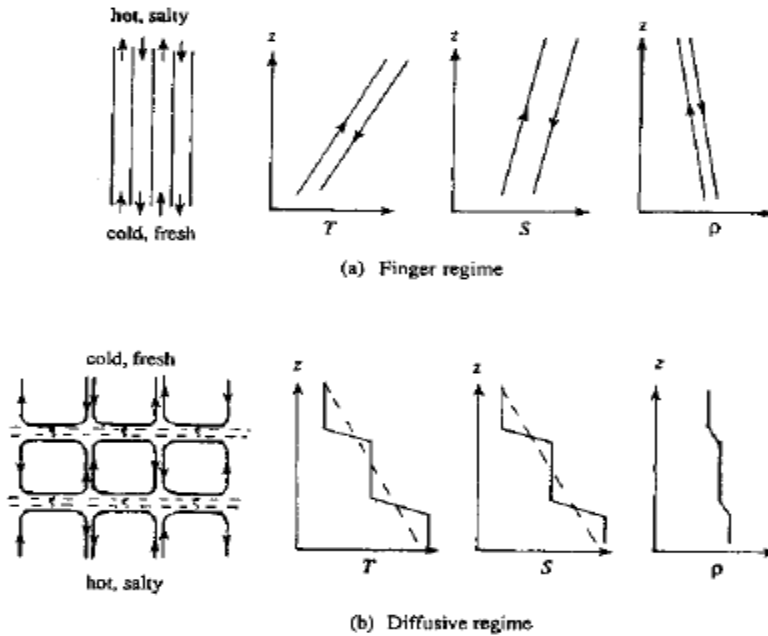

Fig. 11.7 Two kinds of double-diffusive instabilities. (a) Finger instability, showing up- and down-going salt fingers and their temperature, salinity, and density. Arrows indicate direction of motion. (b) Oscillating instability, finally resulting in a series of convecting layers separated by "diffusive" interfaces. Across these interfaces T and S vary sharply, but heat is transported much faster than salt.

Fig. 11.8 Salt fingers, produced by pouring salt solution on top of a stable temperature gradient. Flow visualization by fluorescent dye and a horizontal beam of light. [From Turner (1985).]

(c) Centrifugal instability: Taylor Problem

Bernard Instability: buoyant force $>$ viscous force

Taylor Instability: Couette flow between two rotating cylinders where centrifugal force (outward

from center opposed to centripetal force) > viscous force.

$$Ta = \frac{r_i c (\Omega_i^2 - \Omega_o^2)}{v^2} \quad c = r_o - r_i \ll r_i$$

= centrifugal force / viscous force

$$Ta_{cr} = 1708 \quad \alpha_{cr} c = 3.12 \quad \rightarrow \quad \lambda_{cr} = 2c$$

$$Ta_{trans} = 160,000$$

Square counter rotating vortex pairs with helix streamlines

Fig. 11.10 Definition sketch of instability in rotating Couette flow.

Fig. 11.11 G. I. Taylor's observation and narrow-gap calculation of marginal stability in rotating Couette flow of water. The ratio of radii is $R_2/R_1 \approx 1.14$. The region above the curve is unstable. The dashed line represents Rayleigh's inviscid criterion, with the region to the left of the line representing instability.

Fig. 11.12 Instability of rotating Couette flow. Panels a, b, c, and d correspond to increasing Taylor number. [From Coles (1965).]

(d) Gortler Vortices

Longitudinal vortices in concave curved wall boundary layer induced by centrifugal force and related to swirling flow in curved pipe or channel induced by radial pressure gradient and discussed later with regard to minor losses.

For $\delta/R > .02 \sim .1$ and $Re_\delta = U\delta/\nu > 5$

Fig. 11.13 Görtler vortices in a boundary layer along a concave wall.

(e) Kelvin-Helmholtz instability

Instability at interface between two horizontal parallel streams of different density and velocity with heavier fluid on bottom, or more generally $\rho = \text{constant}$ and $U = \text{continuous}$ (i.e. shear layer instability e.g. as per flow separation). Former case, viscous force overcomes stabilizing density stratification.

$$g(\rho_2^2 - \rho_1^2) < \alpha \rho_1 \rho_2 (U_1 - U_2)^2 \rightarrow c_i > 0 \text{ (unstable)}$$

$U_1 \neq U_2$ large α i.e. short λ always unstable

Vortex Sheet

$$\rho_1 = \rho_2 \rightarrow c_i = \frac{1}{2}(U_1 + U_2) > 0$$

Therefore always unstable

Fig. 11.14 Discontinuous shear across a density interface.

Fig. 11.16 Kelvin-Helmholtz instability generated by tilting a horizontal channel containing two liquids of different densities. The lower layer is dyed. Mean flow in the lower layer is down the plane and that in the upper layer is up the plane. [From Thorpe (1971).]

Fig. 11.17 Billow cloud near Denver, Colorado. [From Drazin and Reid (1981).]

(2) Transition from laminar to turbulent flow

Not all laminar flows have different equilibrium states, but all laminar flows for sufficiently large Re become unstable and undergo transition to turbulence.

Transition: change over space and time and Re range of laminar flow into a turbulent flow.

$$Re_{cr} = \frac{U\delta}{\nu} \sim 1000 \quad \delta = \text{transverse viscous thickness}$$

$$Re_{trans} > Re_{cr} \quad \text{with} \quad x_{trans} \sim 10-20 x_{cr}$$

Small-disturbance (linear) stability theory can predict Re_{cr} with some success for parallel viscous flow such as plane Couette flow, plane or pipe Poiseuille flow, boundary layers without or with pressure gradient, and free shear flows (jets, wakes, and mixing layers).

Note: No theory for transition, but recent DNS helpful.

Outline linearized stability theory for parallel viscous flows: select basic solution of interest; add disturbance; derive disturbance equation; linearize and simplify; solve for eigenvalues; interpret stability conditions and draw thumb curves.

$$\begin{aligned} \bar{u} + \hat{u} & & \bar{u}, \bar{v} &= \text{mean flow, which is solution steady NS} \\ \bar{v} + \hat{v} & & & \\ \bar{p} + \hat{p} & & \hat{u}, \hat{v} &= \text{small 2D oscillating in time disturbance is} \\ & & & \text{solution unsteady NS} \end{aligned}$$

$$\begin{aligned} \hat{u}_t + \bar{u} \hat{u}_x + \bar{u} \hat{u}_x + \bar{v} \hat{u}_y + \bar{v} \hat{u}_y &= -\frac{1}{\rho} \hat{p}_x + \nu \nabla^2 \hat{u} \\ \hat{v}_t + \bar{u} \hat{v}_x + \bar{u} \hat{v}_x + \bar{v} \hat{v}_y + \bar{v} \hat{v}_y &= -\frac{1}{\rho} \hat{p}_x + \nu \nabla^2 \hat{v} \\ \hat{u}_x + \hat{v}_x &= 0 \end{aligned}$$

Linear PDE for $\hat{u}, \hat{v}, \hat{p}$ for $(\bar{u}, \bar{v}, \bar{p})$ known.

Assume disturbance is sinusoidal waves propagating in x direction at speed c: Tollmien-Schlichting waves.

$$\begin{aligned} \hat{\Psi}(x, y, t) &= \phi(y) e^{i\alpha(x-ct)} & \text{Stream function} \\ \hat{u} = \frac{\partial \hat{\Psi}}{\partial y} &= \phi' e^{i\alpha(x-ct)} & y = \text{distance across} \\ & & \text{shear layer} \\ \hat{v} = -\frac{\partial \hat{\Psi}}{\partial x} &= -i\alpha \phi e^{i\alpha(x-ct)} \end{aligned}$$

$$\hat{u}_x + \hat{v}_y = 0 \quad \text{Identically!}$$

$$\alpha = \alpha_r + i\alpha_i = \text{wave number} = 2\pi/\lambda$$

$$c = c_r + ic_i = \text{wave speed} = \omega/\alpha$$

Where $\lambda =$ wave length and $\omega =$ wave frequency

Temporal stability:

Disturbance ($\alpha = \alpha_r$ only and c_r real)

$c_i > 0$	unstable
$= 0$	neutral
< 0	stable

Spatial stability:

Disturbance ($c\alpha =$ real only)

$\alpha_i < 0$	unstable
$= 0$	neutral
> 0	stable

Inserting \hat{u}, \hat{v} into small disturbance equations and eliminating \hat{p} results in Orr-Sommerfeld equation:

inviscid Raleigh equation

$$\overbrace{(u-c)(\phi'' - \alpha^2 \phi) - u'' \phi} = -\frac{i}{\alpha Re} (\phi^{IV} - 2\alpha^2 \phi'' + \alpha^4 \phi)$$

$$u = \bar{u} / U \quad Re = UL/v \quad y = y/L$$

4th order linear homogeneous equation with homogenous boundary conditions (not discussed here) i.e. eigen-value problem, which can be solved albeit not easily for specified geometry and $(\bar{u}, \bar{v}, \bar{p})$ solution to steady NS.

Fig. 11.23 Marginal stability curve for a shear layer $u = U_0 \tanh(y/L)$.

Fig. 11.24 Sketch of marginal stability curves for a boundary layer with favorable and adverse pressure gradients.

TABLE 11.1 Linear Stability Results of Common Viscous Parallel Flows

Flow	$U(y)/U_0$	Re_{cr}	Remarks
Jet	$\text{sech}^2(y/L)$	4	
Shear layer	$\tanh(y/L)$	0	Always unstable
Blasius		520	Re based on δ^*
Plane Poiseuille	$1 - (y/L)^2$	5780	$L = \text{half width}$
Pipe flow	$1 - (r/R)^2$	∞	Always stable
Plane Couette	y/L	∞	Always stable

Although difficult, methods are now available for the solution of the O-S equation. Typical results as follows

FIGURE 5-8
 Amplification curves for the Blasius flat-plate boundary layer. [After Wazzan, Okamura, and Smith (1968a).]

(1) Flat Plate BL:

$$Re_{crit} = \frac{U\delta^+}{\nu} = 520$$

(2) $\alpha\delta^* = 0.35$

$$\rightarrow \lambda_{min} = 18 \delta^* = 6 \delta \text{ (smallest unstable } \lambda)$$

\therefore unstable T-S waves are quite large

(3) $c_i = \text{constant}$ represent constant rates of damping ($c_i < 0$) or amplification ($c_i > 0$). $c_{i \text{ max}} = .0196$ is small compared with inviscid rates indicating a gradual evolution of transition.

(4) $(c_r/U_0)_{\max} = 0.4 \rightarrow$ unstable wave travel at average velocity.

(5) $Re_{\delta^* \text{crit}} = 520 \rightarrow Re_{x \text{ crit}} \sim 91,000$

Exp: $Re_{x \text{ crit}} \sim 2.8 \times 10^6$ ($Re_{\delta^* \text{crit}} = 2,400$) if care taken, i.e., low free stream turbulence

Fig. 11.26 Marginal stability curve for a Blasius boundary layer. Theoretical solutions of Shen and Schlichting are compared with experimental data of Schubauer and Skramstad.

FIGURE 5-12
 Correlation of the critical Reynolds number with the profile shape factor for laminar flow.

FIGURE 5-24
 The classic pipe-flow dye experiment of Reynolds (1883): (a) low speed: laminar flow; (b) high speed: turbulent flow; (c) spark photograph of condition (b).

Our overall picture of the transition process in quiet flow past a smooth flat plate consists of the following processes as one moves downstream:

development of region of high localized shear

- 1 Stable laminar flow near the leading edge
- 2 Unstable two-dimensional Tollmien-Schlichting waves
- 3 Development of three-dimensional unstable waves and hairpin eddies
- 4 Vortex breakdown at regions of high localized shear
- 5 Cascading vortex breakdown into fully three-dimensional fluctuations
- 6 Formation of turbulent spots at locally intense fluctuations
- 7 Coalescence of spots into fully turbulent flow

Extent and details of these processes depends on Re and many other factors (geometry, pg , free-stream, turbulence, roughness, etc).

Rapid development of spanwise flow, and initiation of nonlinear processes

FIGURE 5-25 Development of spanwise variations in the streamwise velocity fluctuation downstream of a vibrating ribbon with spacers. [After Klebanoff, Tilstrom, and Sargent (1962).]

- stretched vortices disintegrate
- cascading breakdown into families of smaller and smaller vortices
- onset of turbulence

FIGURE 5-26 Plan and elevation of the measured growth of a turbulent spot. [After Schubauer and Klebanoff (1955).]

Note: apg may undergo much more abrupt transition. However, in general, pg effects less on transition than on stability

FIGURE 5-27 Idealized sketch of transition process on a flat plate.
